(Received February 2, 2008)

We propose a simple theoretical model for a molecular chemical engine that catalyzes a chemical reaction and converts the free energy released by the reaction into mechanical work. Binding and unbinding processes of reactant and product molecules to and from the engine are explicitly taken into account. The work delivered by the engine is calculated analytically for infinitely slow (“pseudo-static”) processes, which can be reversible (quasi-static) or irreversible, controlled by an external agent. It is shown that the work larger than the maximum value limited by the second law of thermodynamics can be obtained in a single cycle of operation by chance, although the statistical average of the work never exceeds this limit and the maximum work is delivered if the process is reversible. The mechanism of the energy transduction is also discussed.

KEYWORDS: molecular chemical engine, quasi-static process, the second law of thermodynamics, energy transduction

1. Introduction

Biological molecular motors, such as myosin, kinesin, dynein and F₁-ATPase, are tiny machines that catalyze the hydrolysis reaction of adenosine triphosphate (ATP) and convert the free energy released by the reaction into mechanical work.^{1–3} The mechanisms of energy transduction in these *molecular chemical engines* are not fully understood. A simple, idealized model of a molecular chemical engine, like the Carnot cycle of a heat engine, would provide clear understanding of the energy transduction in biomolecular motors and insights into the design of artificial nanomachines. The purpose of the present paper is to propose such a model.

The theoretical models that have been proposed to study how the chemical free energy can be converted into mechanical work may be grouped into two classes. One class of models^{4,5} introduce a “reaction (or chemical) coordinate” x as well as a “mechanical coordinate” y . The former coordinate describes how the chemical reaction proceeds (the increase of x by, say, a will correspond to the consumption of one fuel molecule due to the reaction) and the latter indicates how the engine translocates along a linear track (with a periodic structure of period b) or how the rotor in the engine rotates ($b = 2\pi$). The “mechano-chemical coupling” is expressed as a potential function $U(x, y)$ that satisfies $U(x+a, y) = U(x, y) + \Delta G$ and $U(x, y+b) = U(x, y)$, where $\Delta G < 0$ is the change in the free energy of the reservoir containing fuel and product molecules due to the reaction of a single fuel molecule. In this approach, the binding of a fuel molecule to and the unbinding of a product molecule from the engine are not taken account explicitly. As a result, the reservoir comes into play only through ΔG , which is unsatisfactory because the chemical potentials (or the densities) of fuel and product molecules can affect independently the performance of the engine, as one might expect or we shall see in this paper.

The other class of models deal with transitions between discrete chemical states j ($j = 1, 2, \dots, n$). This class can be divided into two subclasses according to whether the mechanical coordinate is discretized⁶ or continuous.^{7–10} In the former, the value of the mechanical coordinate is determined uniquely by the chemical state, and hence a transition results in a translation of the engine (motor) or a rotation of the rotor. In the latter, the engine in state j undergoes Brownian motion under the influence of state-dependent potential $U_j(y)$ associated with the mechanical coordinate y , and the transition from one state to another does not accompany the translational or rotational motion of the engine at the instance of transition. In this class of models, the binding of a reactant molecule to the engine, the chemical reaction, or the unbinding of a product molecule from the engine trigger a transition between particular states. However, the mechanism of energy transduction is not quite transparent in the previous works on these models.

In the present work we take a combined approach: a continuous reaction coordinate is used to describe the chemical reaction catalyzed by the engine, and discrete chemical states are introduced to distinguish the state of the engine with a fuel or product molecule bound to it from the state with no bound molecule, while a continuous mechanical coordinate denotes the rotation of a rotor connected to the engine. In constructing the model proposed here, we are inspired by the models for F₁-ATPase, a biological rotary motor, by Wang and Oster⁸ and by Kinoshita et al.¹⁰ This protein machine is remarkable in that it works not only as a motor^{11,12} (when ATP molecules are consumed) but also as a generator^{13,14} (ATP molecules are generated when it is forced to rotate in the reverse direction), just as a heat engine works as a heat pump when it is run in the reverse direction. The minimal ingredients necessary to build a reversible molecular chemical engine are extracted from their models^{8,10} and an assumption on the chemical reaction is

*E-mail address: sasaki@camp.apph.tohoku.ac.jp.

introduced to simplify the analysis.

Our model is simple enough to analytically work out extremely slow processes controlled externally, which are analogous to the Carnot cycle of a heat engine. We will call such a process a *pseudo-static* process instead of a *quasi-static* process, because it turns out that such a slow process is not always reversible in the thermodynamic sense. It will be shown that the average work delivered by the engine is identical to the free energy ($-\Delta G > 0$) released by the chemical reaction if the process is reversible, and it is less than $|\Delta G|$ if the process is irreversible; this result is consistent with the laws of thermodynamics. However, it is found that in a single cycle of operation, work larger than the maximum work imposed by thermodynamics can be obtained by chance if the process is irreversible.

In the present model it is the torque resulting from the interaction between the engine and a bound (fuel or product) molecule that contributes to the net mechanical work delivered in a cycle of pseudo-static process, and this torque is independent of the chemical potentials of fuel and product molecules in the reservoir (i.e., independent of ΔG). It will become clear that the chemical potentials determine the “timings” of the binding and unbinding of fuel and product molecules, thereby controlling the interval over which the torque is in effect. Thus the amount of work delivered by the engine is affected by the densities of fuel and product molecules in the reservoir.

2. Model

We wish to construct a simple model for a molecular chemical engine that is supposed to utilize a hypothetical chemical reaction

The setting we assume for the engine to work is as follows. The engine is coupled to a rotor, whose rotational angle θ can be controlled by an external agent. The engine exchanges molecules A and B with a reservoir that contains a large number of these molecules. The chemical potentials μ_A and μ_B of molecules A and B , respectively, are assumed to satisfy the condition

$$\Delta\mu \equiv \mu_A - \mu_B > 0. \quad (2)$$

The engine and the reservoir is in contact with a heat bath of temperature T . The chemical reaction (1) undergoes only at a “binding site” on the engine, to which a single molecule A or B can be bound, and the engine has only one binding site.

It will be said that the engine is operated *forward* or *backward* depending on whether the angle θ of the rotor is increasing or decreasing. The engine is designed so that it cannot bind a molecule when $\theta = 0 \pmod{2\pi}$. A forward (backward) *cycle* is a process in which θ is increased (decreased) from zero to 2π (-2π); the engine is empty both at the start and the end of a cycle. A forward cycle is expected to proceed as follows. A “fuel” molecule A is bound to the engine. Then a “forward reaction” $A \rightarrow B$ takes place at the binding site. Finally, a “waste” (product) molecule B is released to the reservoir. Meanwhile,

the engine delivers work by exerting torque on the rotor. If the cycle proceeds as expected, the free energy of the reservoir changes by $\Delta G = -\Delta\mu < 0$ and the engine returns to the original state after the cycle. If the laws of thermodynamics can be applied to this process, the maximum work the engine can deliver in principle will be $\Delta\mu$.¹⁵

Now we describe in detail how our model is constructed.

2.1 Ligands

Molecules A and B are thought of as two stable states of a single molecule, which will be referred to as a *ligand*, with different geometrical structures. It is assumed that a continuous transformation of structure from A to B can be characterized by a single, dimensionless parameter r , a “reaction coordinate.”

The energy profile associated with the structural change of a ligand molecule $U(r)$ may be defined, apart from an unimportant additive constant, by

$$\exp[-\beta U(r)] = \text{Tr} \exp[-\beta H_L(r)], \quad (3)$$

where $\beta = 1/k_B T$ with k_B being the Boltzmann constant and $H_L(r)$ is the Hamiltonian for the vibrational and rotational modes of a ligand molecule under the constraint that the reaction coordinate r is held fixed; we assume that r can be treated as a classical dynamical variable. In the definition (3) of $U(r)$, we have assumed, for simplicity, that the reservoir is an ideal gas mixture of molecules A and B . If the reservoir is a dilute solution where A and B are solutes, the interaction of a ligand with solvent molecules should be taken into account in defining $U(r)$. Once $U(r)$ is defined appropriately, the discussions presented below will be valid irrespective of whether the reservoir is an ideal gas or a dilute solution.

In order for molecules A and B to be stable, $U(r)$ must have two minima, say at $r = r_A$ and $r = r_B$, corresponding to molecules A and B . The height of potential barrier separating these minima should be much larger than the thermal energy $k_B T$ so that reaction (1) does not occur spontaneously in the reservoir.

Let n_A and n_B be the densities (numbers of molecules per unit volume) of molecules A and B , respectively, in the reservoir. Then the chemical potentials of A and B are given by

$$\mu_\alpha = U_\alpha + k_B T \ln \frac{n_\alpha}{\eta_\alpha} \quad (\alpha = A, B), \quad (4)$$

where $U_\alpha = U(r_\alpha)$, and η_α is a quantity that has dimensions of density and is proportional to a restricted partition function associated with the reaction coordinate:

$$\eta_\alpha \propto \int_{\mathcal{R}_\alpha} \exp\{-\beta[U(r) - U_\alpha]\} dr \quad (\alpha = A, B). \quad (5)$$

Here, $\mathcal{R}_\alpha$ is a small interval around $r = r_\alpha$ on the r axis; if $U(r)$ can be approximated by $U(r) = U_\alpha + \frac{1}{2}K_\alpha(r - r_\alpha)^2$ with a positive constant K_α in the vicinity of r_α , we will have $\eta_\alpha \propto (2\pi\beta/K_\alpha)^{1/2}$.

Fig. 1. The conformational change of the engine upon the rotation of the rotor is schematically shown. The bold arrows indicate the direction of a forward operation. (a) $\theta \sim 0$, (b) $0 < \theta < \theta_1$, (c) $\theta \sim \theta_1$, (d) $\theta_1 < \theta < \theta_2$, (e) $\theta \sim \theta_2$, (f) $\theta_2 < \theta < 2\pi$.

2.2 Engine with no ligand

As already explained, the engine is coupled to a rotor (through an arm-like structure, for example). We imagine that the engine is a macromolecule like a biological molecular motor and assume that its structure (conformation) changes with the rotation of the rotor. In this subsection we consider the case that the engine carries no ligand molecule.

Let $H_0(\theta)$ be the Hamiltonian of the engine with no ligand under the condition that the rotation angle of the rotor remains fixed to be θ . The potential (free energy) $V_0(\theta)$ of the engine under this condition is defined by

$$\exp[-\beta V_0(\theta)] = \text{Tr} \exp[-\beta H_0(\theta)]. \quad (6)$$

It is assumed that the engine is operated (θ is varied by the external agent) so slowly that it is in thermal equilibrium at any instant. Then the torque $\tau_0(\theta)$ exerted by the engine on the rotor is given as the statistical average of $-\partial H_0(\theta)/\partial \theta$, which implies

$$\tau_0(\theta) = -\frac{dV_0(\theta)}{d\theta}. \quad (7)$$

Obviously, $V_0(\theta)$ and $\tau_0(\theta)$ possess the following periodicity:

$$V_0(\theta + 2\pi) = V_0(\theta), \quad \tau_0(\theta + 2\pi) = \tau_0(\theta). \quad (8)$$

In order that the engine works properly and can be analyzed without much difficulty we require the engine to possess the following properties associated with its conformational change. Let θ_1 and θ_2 be some constants satisfying $0 < \theta_1 < \theta_2 < 2\pi$. When the angle θ of the rotor is in the interval $0 < \theta < \theta_1$, only molecule A can be attached to or detached from the binding site of the engine; if $\theta_1 < \theta < \theta_2$, no ligand can be attached or detached; and when $\theta_2 < \theta < 2\pi$, only molecule B can be attached or detached. This can be made possible if, for example, the engine has a window-like structure and a ligand can reach the binding site only by going through the opening of the window (see Fig. 1): when $0 < \theta < \theta_1$, the opening of the window has a shape such

Fig. 2. Potential $W(\theta, r)$ defined by eq. (9) as a function of r for fixed values of θ . (a) $\theta \sim 0$, (b) $0 < \theta < \theta_1$, (c) $\theta \sim \theta_1$, (d) $\theta_1 < \theta < \theta_2$, (e) $\theta \sim \theta_2$, (f) $\theta_2 < \theta < 2\pi$.

that a molecule A can go through it but a molecule B cannot; the window is closed if $\theta_1 < \theta < \theta_2$ or $\theta \sim 0$; and when $\theta_2 < \theta < 2\pi$, the shape of the opening allows a molecule B but not a molecule A to go through it.

2.3 Engine with a ligand

Now we consider the case that a ligand molecule is bound to the engine. Let $H_{\text{int}}(\theta, r)$ be the interaction between the engine and the ligand under the constraint that the angle θ of the rotor and the reaction coordinate r of the ligand are held fixed. We define potential $W(\theta, r)$ by

$$\begin{aligned} \exp\{-\beta[V_0(\theta) + W(\theta, r)]\} \\ = \text{Tr} \exp\{-\beta[H_0(\theta) + H_L(r) + H_{\text{int}}(\theta, r)]\}, \end{aligned} \quad (9)$$

where $V_0(\theta)$ has been defined in eq. (6). Roughly speaking, W is the sum of the ligand energy and the engine-ligand interaction.

The performance of the engine depends crucially on potential $W(\theta, r)$. Let us describe the desired dependence of $W(\theta, r)$ on r for fixed values of θ (see Fig. 2). If the angle of the rotor is in interval $0 < \theta < \theta_1$, W should have a deep well around $r = r_A$ so that a molecule A sitting at the binding site stays there as molecule A without being converted to molecule B; it may have another minimum around $r = r_B$ separated by a large barrier. Similarly, we require that W should have a deep well around $r = r_B$ if $\theta_2 < \theta < 2\pi$, so that molecule B is stable at the binding site. A ligand bound to the engine is supposed to undergo forward reaction $A \rightarrow B$ if θ is varied from θ_1 to θ_2 or backward reaction $B \rightarrow A$ if θ is varied from θ_2 to θ_1 . In this regard it is demanded that W has only one minimum around $r = r_A$ for $\theta \sim \theta_1$, and only one minimum around $r = r_B$ for $\theta \sim \theta_2$. For $\theta_1 < \theta < \theta_2$, W may have a single minimum at some r between r_A and r_B , and its location moves continuously as θ is varied between θ_1 and θ_2 ; or W may have a secondary minimum slightly above the primary one separated by a barrier whose height is much less than $k_B T$.

For the sake of simplicity the relaxation of the reaction coordinate r is assumed to occur quickly enough that this degree of freedom is always in thermal equilibrium

during an operation of the engine. Then we can think of an “effective interaction” $\epsilon(\theta)$ defined by

$$\exp[-\beta\epsilon(\theta)] = \int_{\mathcal{R}(\theta)} \exp[-\beta W(\theta, r)] dr, \quad (10)$$

where the range $\mathcal{R}$ of integral depends on θ as follows: $\mathcal{R}$ is the entire range of r for $\theta_1 < \theta < \theta_2$, $\mathcal{R} = \mathcal{R}_A$ [small interval around $r = r_A$ introduced in eq. (5)] for $0 < \theta < \theta_1$, and $\mathcal{R} = \mathcal{R}_B$ for $\theta_2 < \theta < 2\pi$. The reason why the integral range is restricted to $\mathcal{R}_A$ for $0 < \theta < \theta_1$ is that W as a function of r may have a valley around $r = r_B$ as mentioned above but this valley cannot be visited due to the large barrier separating it from the valley around $r = r_A$. For the similar reason the integral range is restricted to $\mathcal{R}_B$ for $\theta_2 < \theta < 2\pi$. Because of these restrictions on the integral range in eq. (10), $\epsilon(\theta)$ is discontinuous at $\theta = 0 \pmod{2\pi}$ in general, though it is periodic, $\epsilon(\theta + 2\pi) = \epsilon(\theta)$. It is not difficult to see that the engine carrying a ligand exerts torque

$$\tau_1(\theta) = -\frac{dV_0(\theta)}{d\theta} - \frac{d\epsilon(\theta)}{d\theta} \quad (11)$$

on the rotor when its rotational angle is θ ; it is the statistical average of $-\partial[H_0(\theta) + H_{\text{int}}(\theta, r)]/\partial\theta$.

2.4 Binding and unbinding of a ligand

Suppose that the rotational angle θ of the rotor is in range $0 < \theta < \theta_1$. Then the binding site of the engine can be empty or occupied by a molecule A . If the binding-unbinding process is in equilibrium, the probability $p_A(\theta)$ that a molecule A is bound to the engine is given by

$$p_A(\theta) = \frac{Z_1(\theta) \exp(\beta\mu_A)}{Z_0(\theta) + Z_1(\theta) \exp(\beta\mu_A)}, \quad (12)$$

where Z_0 and Z_1 are, respectively, the partition functions of the engine without and with a ligand. From the definitions of $V_0(\theta)$ and $\epsilon(\theta)$ we have

$$Z_0(\theta) = \exp[-\beta V_0(\theta)], \quad (13)$$

$$Z_1(\theta) = \exp\{-\beta[V_0(\theta) + \epsilon(\theta)]\}, \quad (14)$$

and therefore eq. (12) can be expressed as

$$p_A(\theta) = \frac{1}{\exp\{\beta[\epsilon(\theta) - \mu_A]\} + 1} \quad (0 < \theta < \theta_1). \quad (15)$$

Similarly, we have

$$p_B(\theta) = \frac{1}{\exp\{\beta[\epsilon(\theta) - \mu_B]\} + 1} \quad (\theta_2 < \theta < 2\pi) \quad (16)$$

for the probability that a molecule B is bound to the engine when θ is in interval $\theta_2 < \theta < 2\pi$.

We have assumed that the engine is designed so that a ligand cannot be bound when $\theta = 0 \pmod{2\pi}$. Considering eqs. (15) and (16), this requirement implies that

$$\exp\{-\beta[\epsilon(0+) - \mu_A]\} = 0, \quad (17)$$

$$\exp\{-\beta[\epsilon(2\pi-) - \mu_B]\} = 0. \quad (18)$$

(Remember that in general $\epsilon(\theta)$ is discontinuous at $\theta = 0$, i.e., $\epsilon(0+) \neq \epsilon(2\pi-)$.) In reality these conditions cannot be satisfied exactly, because ϵ cannot be infinite. We consider eqs. (17) and (18) as mathematical idealization for a situation in which the left-hand sides of these equations

Fig. 3. An example of effective interaction $\epsilon(\theta)$ between the engine and a bound ligand defined by eq. (10). Binding and unbinding transitions of a molecule A occurs for $0 < \theta < \theta_1$. Chemical reaction $A \rightleftharpoons B$ undergoes if a ligand is bound for $\theta_1 < \theta < \theta_2$; in this interval both binding and unbinding of a ligand is prohibited. Binding and unbinding transitions of a molecule B take place for $\theta_2 < \theta < 2\pi$.

are extremely small and can be treated as zero practically.

Figure 3 shows an example of “effective interaction” $\epsilon(\theta)$ between the engine and a ligand that satisfies conditions (17) and (18) and certain properties we are going to discuss. When the engine is operated forward, it is preferable that probability $p_A(\theta)$ increases as θ is increased from zero to θ_1 , while $p_B(\theta)$ decreases as θ is varied from θ_2 to 2π . Hence, we assume that $\epsilon(\theta)$ decreases with increasing θ for $0 < \theta < \theta_1$ and increases with θ for $\theta_2 < \theta < 2\pi$. The dependence of ϵ on θ for $\theta_1 < \theta < \theta_2$ can be rather arbitrary, because binding or unbinding of a ligand is prohibited in this interval.

If the chemical potential μ_A of molecule A lies well above $\epsilon_1 \equiv \epsilon(\theta_1)$, the engine carries a molecule A with large probability when θ reaches θ_1 in a forward operation. Similarly, the engine carries a molecule B with large probability when θ is decreased to θ_2 in a backward operation if μ_B lies well above $\epsilon_2 \equiv \epsilon(\theta_2)$. These conditions are favorable for good performance of the engine. We shall not assume, however, that these are always satisfied, because we are interested in how the engine may work under poor conditions as well as ideal ones.

3. Pseudo-Static Operations of the Engine

Let us analyze the work delivered by the engine when it is operated slowly enough that the binding and unbinding of ligands is in equilibrium at almost any instance of the operation. We call this process a *pseudo-static* process to distinguish it from a *quasi-static* process; the latter is preserved for a reversible process, while the former may be reversible or irreversible as we shall see. In a pseudo-static process the probability that the engine carries a ligand is given by eq. (15) for $0 < \theta < \theta_1$ and by eq. (16) for $\theta_2 < \theta < 2\pi$, and the torque exerted on the rotor by the engine is given by

$$\tau(\theta) = [1 - p_A(\theta)]\tau_0(\theta) + p_A(\theta)\tau_1(\theta) \quad (19)$$

for $0 < \theta < \theta_1$ and by

$$\tau(\theta) = [1 - p_B(\theta)]\tau_0(\theta) + p_B(\theta)\tau_1(\theta) \quad (20)$$

for $\theta_2 < \theta < 2\pi$, where τ_0 and τ_1 are defined in eqs. (7) and (11), respectively. These expressions for the torque can be rewritten as

$$\tau(\theta) = -\frac{d}{d\theta} \left\{ V_0(\theta) + \frac{1}{\beta} \ln[1 - p_\alpha(\theta)] \right\}, \quad (21)$$

where $\alpha = A$ for $0 < \theta < \theta_1$ and $\alpha = B$ for $\theta_2 < \theta < 2\pi$. Note that the quantity in the braces in eq. (21) is identical to the grand potential (grand-canonical free energy) of the engine.¹⁶ For $\theta_1 < \theta < \theta_2$ the torque is given by $\tau(\theta) = \tau_0(\theta)$ or $\tau(\theta) = \tau_1(\theta)$ depending on whether the engine carries no ligand or one.

3.1 Forward operation

In a forward, pseudo-static operation of the engine the external agent is supposed to control the angle θ of the rotor to increase extremely slowly. The work delivered by the engine in one cycle of forward operation is given by

$$W_{\text{fw}} = \int_0^{2\pi} \tau(\theta) d\theta, \quad (22)$$

where $\tau(\theta)$ is the torque exerted by the engine.

We divide one cycle of a forward operation into three phases: the period in which $0 < \theta < \theta_1$ will be called “phase A,” the period of $\theta_1 < \theta < \theta_2$ “phase C,” and the last one ($\theta_2 < \theta < 2\pi$) “phase B.” In phase A the torque exerted by the engine is given by eq. (21) with $\alpha = A$, and therefore the work delivered in this phase is found to be

$$W_{\text{fw}}^A = V_0(0) - V_0(\theta_1) - \frac{1}{\beta} \ln(1 - p_1), \quad (23)$$

where probability p_1 is defined by

$$p_1 = p_A(\theta_1). \quad (24)$$

Condition (17) has been used in deriving eq. (23). The work W_{fw}^B obtained in phase B can be worked out similarly. Using expression (21) with $\alpha = B$ and condition (18), we get

$$W_{\text{fw}}^B = V_0(\theta_2) - V_0(2\pi) + \frac{1}{\beta} \ln(1 - p_2), \quad (25)$$

where probability p_2 is defined by

$$p_2 = p_B(\theta_2). \quad (26)$$

In phase C there are two alternatives: if the engine carries no ligand, the work delivered in this phase is

$$W_{\text{fw}}^{C0} = V_0(\theta_1) - V_0(\theta_2) \quad (27)$$

since the torque is given by $\tau_0(\theta)$; and if a ligand is bound to the engine, the work is given by

$$W_{\text{fw}}^{C1} = V_0(\theta_1) - V_0(\theta_2) + \epsilon(\theta_1) - \epsilon(\theta_2) \quad (28)$$

since the torque is $\tau_1(\theta)$. Summing up the contributions from the three phases, we obtain

$$W_{\text{fw}}^0 = \frac{1}{\beta} \ln \frac{1 - p_2}{1 - p_1} \quad (29)$$

for the work delivered in a cycle in the case that the engine carries no ligand in phase C. If the engine carries a ligand in phase C, the work in one cycle is given by

$$W_{\text{fw}}^1 = \Delta\mu + \frac{1}{\beta} \ln \frac{p_2}{p_1}. \quad (30)$$

Let us examine the results for W_{fw}^0 and W_{fw}^1 obtained above. It is noted that depending on the design of the engine and/or the preparation of the reservoir any of the cases (i) $p_1 = p_2$, (ii) $p_1 < p_2$, and (iii) $p_1 > p_2$ can be realized. In the first case we have

$$W_{\text{fw}}^0 = 0, \quad W_{\text{fw}}^1 = \Delta\mu. \quad (31)$$

This consequence is in accordance with our naive expectation that the engine delivers no work if it does not catalyze the chemical reaction, and the free energy $\Delta\mu$ released in reaction $A \rightarrow B$ is converted into mechanical work if the engine catalyzes the reaction. In the case of $p_1 < p_2$ one finds

$$W_{\text{fw}}^0 < 0, \quad W_{\text{fw}}^1 > \Delta\mu. \quad (32)$$

Note that the second inequality tells that *work greater than the the maximum work dictated by the second law of thermodynamics can be extracted in one cycle of operation*. Apparent violation of the second law may occur also in the case of $p_1 > p_2$, in which we observe

$$W_{\text{fw}}^0 > 0, \quad W_{\text{fw}}^1 < \Delta\mu. \quad (33)$$

The first inequality implies that the heat extracted from a single heat bath can be converted into mechanical work without leaving any changes in the engine and the reservoir of ligand molecules, which appears to be in contradiction to the second law.

The fact that the engine can deliver work larger than what is expected from thermodynamics in one cycle of operation does not necessarily mean inadequacy of the present model. This is because such an event occurs stochastically and in an uncontrollable manner. In the case of $p_1 < p_2$, for example, the work delivered may be larger than the maximum work limited by thermodynamics ($W_{\text{fw}}^1 > \Delta\mu$) in one cycle but it may be less than the maximum work ($W_{\text{fw}}^0 < 0$) in another. Therefore, the appropriate quantity to be worked out should be the average work per cycle in a forward operation carried out over many cycles. In a forward operation the probability that a ligand is bound in phase C is given by p_1 . Hence, the average work delivered per cycle is

$$W_{\text{fw}} = (1 - p_1)W_{\text{fw}}^0 + p_1W_{\text{fw}}^1 = p_1\Delta\mu - \frac{1}{\beta}f(p_1, p_2), \quad (34)$$

where function $f(x, y)$ is defined by

$$f(x, y) = (1 - x) \ln \frac{1 - x}{1 - y} + x \ln \frac{x}{y}. \quad (35)$$

It is easy to see that $f(x, y) \geq 0$ for $0 \leq x \leq 1$ and $0 \leq y \leq 1$, where the equality holds if $x = y$. Thus we find

$$W_{\text{fw}} \leq p_1\Delta\mu, \quad (36)$$

where the equality holds if $p_1 = p_2$. If a ligand is bound in phase C of a forward cycle (with probability p_1), a

molecule A in the reservoir will have been transformed into a molecule B when the cycle is completed. This means that the average decrease in the free energy of the reservoir per cycle is given by $p_1\Delta\mu$, which is identical to the right-hand side of eq. (36). Consequently, it turns out that inequality (36) is *consistent with the maximum work theorem of thermodynamics*, and the maximum work is obtained if $p_1 = p_2$.

3.2 Backward operation

The angle θ of the rotor is decreased extremely slowly by the external agent in a pseudo-static, backward operation of the engine. A cycle starts with phase B in which θ is decreased from 2π to θ_2 , and then phase C ($\theta_2 > \theta > \theta_1$) and phase A ($\theta_1 > \theta > 0$) follow. The work delivered by the engine in each phase is obtained from the corresponding work in a forward operation by changing its sign. Consequently, the work in a cycle is given by

$$W_{\text{bw}}^0 = \frac{1}{\beta} \ln \frac{1-p_1}{1-p_2} \quad (37)$$

if a ligand is not bound in phase C , and by

$$W_{\text{bw}}^1 = -\Delta\mu + \frac{1}{\beta} \ln \frac{p_1}{p_2} \quad (38)$$

if a ligand is bound in phase C .

Since a ligand is bound with probability p_2 in phase C of a backward operation, the average work delivered by the engine per cycle turns out to be

$$W_{\text{bw}} = (1-p_2)W_{\text{bw}}^0 + p_2W_{\text{bw}}^1 = -p_2\Delta\mu - \frac{1}{\beta}f(p_2, p_1), \quad (39)$$

where function $f(x, y)$ has been defined in eq. (35). Since $f(x, y) \geq 0$ as remarked earlier, it is concluded from eq. (39) that

$$-W_{\text{bw}} \geq p_2\Delta\mu, \quad (40)$$

where the equality holds if $p_1 = p_2$.

When the engine is operated backwards, it works as a *generator* in the sense that fuel molecules A are generated from waste molecules B . As a result, the free energy of the reservoir is increased. The right-hand side of inequality (40) represents the average increase in the free energy of the reservoir per cycle, while the left-hand side is the work provided by the external agent. Therefore, this inequality tells that the minimum work necessary for converting molecules B into A is equal to the change in the free energy of the reservoir, which is *consistent with the minimum work theorem of thermodynamics*.

3.3 Reversibility

It is evident that a single cycle of a forward or backward operation discussed above cannot be reversible unless $p_1 = p_2 = 1$. Suppose, for example, that a ligand is bound in phase C of a forward cycle and the engine is operated backwards after the cycle is completed. The engine may or may not carry a ligand in phase C of the backward cycle, indicating that individual cycles are not reversible.

A cycle may be reversible, however, in the following statistical sense. Considering the average over many cycles, the probability that the engine carries a ligand in phase C is p_1 in a forward cycle and p_2 in a backward cycle. Therefore, if the condition $p_1 = p_2$ is satisfied, the statistical properties of the whole system (including the engine, the reservoir of ligands, the heat bath and the external agent) at a given value of θ in a forward cycle is exactly the same as that in a backward cycle. This condition of reversibility coincides with the condition for equalities in eqs. (36) and (40) to hold. This observation is consistent with thermodynamics: *the maximum work obtained or the minimum work needed to provide in a process is achieved when the process is reversible*.

It should be remarked that, even in the statistical sense, pseudo-static operations of the engine discussed above are not reversible if $p_1 \neq p_2$. The irreversibility arises when the phase of operation changes from C to B in a forward process, for example: The probability that a ligand is bound to the engine is p_1 for $\theta = \theta_2 - 0$ (phase C), and right after θ is increased across θ_2 it must be relaxed irreversibly towards p_2 , the probability in equilibrium for $\theta = \theta_2 + 0$ (phase B). In a backward cycle the irreversibility comes out upon passing from phase C to phase A . This kind of irreversibility cannot be eliminated no matter how slowly θ is varied. The same kind of irreversibility is discussed in ref. 17, and a similar irreversibility is pointed out¹⁸ to result from the contact of a small system with a heat bath.

4. Mechanism of Energy Transduction

The present model of a molecular chemical engine is simple enough to find out how the engine converts the free energy (2) released by the chemical reaction into mechanical work. The torque exerted by the engine has contributions from the conformational free energy $V_0(\theta)$ of the engine without a ligand and from the effective interaction $\epsilon(\theta)$ between the engine and a bound ligand. It is evident that the ϵ is responsible for net mechanical work in one cycle of operation, because the contribution from V_0 cancels out over a cycle due to its periodicity (8). However, the interaction $\epsilon(\theta)$ appears to have nothing to do with the chemical potentials μ_A and μ_B of reactant and product molecules, which define the decrease $\Delta\mu$ in the free energy of the reservoir. Then, how the work delivered by the engine may depend on μ_A and μ_B ? We will see that *the chemical potentials affect the “timings” of switching “on” and “off” the interaction $\epsilon(\theta)$, and that the amount of work delivered by the engine during a cycle depends on these timings*.

We first consider an idealized situation in which μ_A lies well above $\epsilon_1 = \epsilon(\theta_1)$ and μ_B well above $\epsilon_2 = \epsilon(\theta_2)$ (see Fig. 3), and $k_B T$ is much smaller than $\mu_A - \epsilon_1$ and $\mu_B - \epsilon_2$. In this circumstance we have $p_1 \simeq 1$ and $p_2 \simeq 1$, and observe that $p_A(\theta)$ increases from zero to one in a narrow region around θ_A defined by $\epsilon(\theta_A) = \mu_A$ as θ is increased from 0 to θ_1 , according to eq. (15). Similarly, $p_B(\theta)$ decreases from one to zero around angle θ_B defined by $\epsilon(\theta_B) = \mu_B$ as θ is increased from θ_2 to 2π . This means that the engine catches a molecule A when θ reaches around θ_A in a forward cycle, and keeps carrying the

ligand afterwards until θ reaches θ_B , where the ligand is released as a molecule B . Hence, the interaction $\epsilon(\theta)$ is switched on around $\theta = \theta_A$ and switched off around $\theta = \theta_B$ in this situation. Consequently, the work delivered by the engine is estimated to be

$$W \simeq \mu_A - \mu_B, \quad (41)$$

because the torque due to $\epsilon(\theta)$ is given by $-\mathrm{d}\epsilon/\mathrm{d}\theta$ [the second term in eq. (11)]. This result is consistent with the rigorous one (30) with $p_1 \simeq 1$ and $p_2 \simeq 1$. In this way, we see that the timings of binding and unbinding of a ligand molecule determined by μ_A and μ_B control the work delivered by the engine: if μ_A is increased, for example, then θ_A decreases and hence the range of θ over which $\epsilon(\theta)$ is on increases; this results in the increase in the work delivered by the engine, since $\epsilon(\theta)$ in this interval yields positive torque.

In the above argument, the temperature is assumed to be low enough that the switching of the interaction $\epsilon(\theta)$ occur sharply around $\theta = \theta_A$ and $\theta = \theta_B$. If the temperature is not so low the switching occur gradually: for example, binding and unbinding of molecule A are repeated many times over a certain range of θ around θ_A . However, we can say that $\epsilon(\theta)$ is switched on at $\theta = \theta_A$ *on average*, because probability p_A given by eq. (15) regarded as a function of $\epsilon(\theta)$ is “antisymmetric” about $\epsilon = \mu_A$: transformation $\epsilon - \mu_A \rightarrow \mu_A - \epsilon$ results in $p_A \rightarrow 1 - p_A$. Similarly, it can be said that $\epsilon(\theta)$ is switched off at θ_B on average as long as $p_2 \simeq 1$. Hence, the argument leading to eq. (41) is still valid even in the case of gradual switching, if the timings of switching are understood as the averaged ones discussed here.

In the idealized situation considered above, the engine works with high efficiency for arbitrary choices of μ_A and μ_B as far as conditions $p_1 \simeq 1$ and $p_2 \simeq 1$ are satisfied: the decrease in the free energy (2) of the reservoir is almost perfectly converted into mechanical work ($W \simeq \Delta\mu$). If either of these conditions is not satisfied, the efficiency is not always good. For example, suppose that μ_B lies well below ϵ_2 ($p_2 \simeq 0$), and μ_A well above ϵ_1 ($p_1 \simeq 1$). In a forward cycle under this extreme circumstance, the engine catch a molecule A at $\theta = \theta_A$ on average (since $p_1 \simeq 1$), and releases a molecule B immediately after the process enters phase B (since $p_2 \simeq 0$). Therefore, potential $\epsilon(\theta)$ is on for $\theta_A < \theta < \theta_2$ on average, and the work delivered in a cycle is estimated as

$$W \simeq \mu_A - \epsilon_2, \quad (42)$$

which is independent of μ_B and less than $\Delta\mu$. This result is consistent with the rigorous one given by (30) with $p_1 \simeq 1$ and $p_2 \simeq \exp[\beta(\mu_B - \epsilon_2)]$, where the latter expression is obtained from eq. (16) under the condition that $p_2 \ll 1$. According to eq. (4), $\Delta\mu$ can become large indefinitely by letting the density of molecule B in the reservoir become vanishingly small ($\mu_B \rightarrow -\infty$). However, the work remains unaltered and the efficiency $W/\Delta\mu$ goes to zero in this limit. A similar, qualitative argument is given in Ref. 10.

Another extreme case of interest may be the situation in which conditions

$$\epsilon_1 > \mu_A > \mu_B > \epsilon_2, \quad (43)$$

$p_1 \ll 1$ and $p_2 \simeq 1$ are satisfied. Such a situation can be realized by lowering the density of fuel molecule in the reservoir. In a forward cycle under this circumstance, a fuel molecule A can be bound to the engine only in the vicinity of $\theta = \theta_1$ (with very small probability). If the engine carries a ligand when the cycle proceeds to phase C , a forward reaction $A \rightarrow B$ takes place and a molecule B will be released around $\theta = \theta_B$ (since $p_2 \simeq 1$). Therefore, the work delivered in this cycle will be

$$W \simeq \epsilon_1 - \mu_B, \quad (44)$$

which is larger than $\Delta\mu = \mu_A - \mu_B$ according to condition (43). This result is again consistent with the rigorous one given by (30) with $p_1 \ll 1$ and $p_2 \simeq 1$, and provides an example in which work larger than the maximum work predicted by thermodynamics can be obtained in a single cycle of forward operation [the second inequality in eq. (32)].

5. Concluding Remarks

We have proposed a simple, idealized model for a molecular chemical engine, and analyzed pseudo-static processes associated with it. The work delivered by the engine in a forward operation (§ 3.1) and the work necessary to operate the engine backwards (§ 3.2) have been calculated analytically. The statistical averages of these works are found to be consistent with the maximum/minimum work theorem of thermodynamics, whereas the work for an individual cycle of operation is not necessarily so. We have also clarified (§ 4) how the densities of fuel and product molecules in the reservoir, which determine the free energy released by the chemical reaction, can affect the work delivered by the engine.

In the present work, we have restricted our attention to pseudo-static processes controlled by an external agent. It is possible to make the model engine constructed here run autonomously (i.e., without the external agent) and do work against a load torque applied to the rotor. The angular velocity of the rotor, the thermodynamic efficiency and other quantities characterizing the performance of the engine are under investigation.

The recent experiment on F₁-ATPase,¹⁴ a biological rotary motor, has clearly shown that it consumes three ATP molecules per turn of the rotor (the γ subunit) in a forward operation, while a forced, reversal rotation of the rotor produces about 2.3 ATP molecules per turn on average. Although the experimental situation cannot be considered as pseudo-static, it would be tempting to compare it with the present analysis. The experimental results mentioned above indicate that $p_1 \simeq 1$ and $p_2 \simeq 0.77$, since F₁-ATPase contains three engines called the β subunits and each engine is thought to be responsible for 120° rotation of the rotor. In our model, probability p_2 depends on the concentration of product molecules in the reservoir. In the case of F₁-ATPase, the product molecules are adenosine diphosphate (ADP) and inorganic phosphate (Pi). The physiological concentrations of ATP and Pi were chosen in the experiment. If our simple model captures the essence of energy transduction in F₁-ATPase, it is predicted that different choices

of ADP and Pi concentrations will result in different values of p_2 (mechano-chemical coupling efficiency); p_2 will increase if these concentrations are increased.

Finally, we mention a few theoretical works that have closely related with the present work. A quasi-static process of a macroscopic chemical engine is discussed in ref. 19. In refs. 17,20 models of molecular motors driven by two reservoirs containing the same kind of particles with different densities; the decrease in the total free energy of the reservoirs resulting from the transfer of particles from the high-density reservoir to the low-density one through the motor is converted into mechanical work. The Carnot cycle for a microscopic heat engine is analyzed in ref. 21.

Acknowledgements

I would like to thank Professor E. Muneyuki for a stimulating discussion, which encourage me to start the present work. I also thank Y. Ito for a number of discussions on the present model in its infancy.
